

Part 0 : data structure (0%)

Whole works are applied in **class Graph**.

Information of edges.csv and heuristic.csv are stored in **graph & heur** (in format of dictionary) by calling `addEdge()` and `addheur()`.

Graph structure	Read data
<pre> from collections import defaultdict from queue import PriorityQueue class Node: def __init__(self, parent = None, id = None, dist = 0.0, speed = 0.0): self.parent = parent self.id = id self.dist = dist self.speed = speed class Graph: def __init__(self): self.graph = defaultdict(list) self.heur = defaultdict(list) def addEdge(self, v1, v2, d, speed): self.graph[v1].append(Node(v1, v2, d, speed)) def addheur(self, v, h1, h2, h3): self.heur[v] = [h1, h2, h3] def bfs(self, src, dst): def dfs(self, src, dst): def ucs(self, src, dst): def astar(self, src, dst, htype): </pre>	<pre> import csv g = Graph() # num(node) = 12326 with open('./edges.csv', newline='') as csvfile: rows = csv.reader(csvfile, delimiter=',') headers = next(rows) for row in rows: v1 = (int)(row[0]) v2 = (int)(row[1]) dist = float(row[2]) speed = float(row[3]) * 1000 / 3600 # m/s g.addEdge(v1, v2, dist, speed) with open('./heuristic.csv', newline='') as csvfile: rows = csv.reader(csvfile, delimiter=',') headers = next(rows) for row in rows: v = (int)(row[0]) h1 = (float)(row[1]) h2 = (float)(row[2]) h3 = (float)(row[3]) g.addheur(v, h1, h2, h3) </pre>

Part 1: BFS (10%)

- (1) Use `set()` to store the visited node_ids, which contains only unique elements.
- (2) The frontier is applied by `queue`, thus here apply `pop(0)` instead of `pop()` due to FIFO.
- (3) What pushed into queue is a `tuple` with 2 elements: ([path_from_src], distance)

Pseudo code	
<p>Visited node set: <code>set()</code></p> <p>Frontier : <code>queue</code></p> <p>Pop the first node in queue:</p> <p> # If the node is visited, just pop it</p> <p> If the node is not visited:</p> <p> Neighbors = <code>expand(node)</code></p> <p> For each neighbor:</p> <p> New_path = [path] + child_node</p> <p> New_dist = <code>dist(node) + edge(node,neighbor)</code></p> <p> <code>queue.put(new_path, new_dist)</code></p> <p> <code>visited.add(node)</code></p>	
code	
<pre>def bfs(self, src, dst): visited = set() q = [[src],0.0] while q: path, cur_dist = q.pop(0) node_id = path[-1] if node_id not in visited: if node_id == dst: return (path,cur_dist,len(visited)) neighs = self.graph[node_id] for neigh in neighs: new_path = list(path) new_path.append(neigh.id) q.append((new_path, cur_dist + neigh.dist)) visited.add(node_id) print("Path not found") return</pre>	<p>The <code>node_id</code> is retrieved from the last element in path.</p> <p>The distance stored in tuple is calculated from src.</p>

Part 2: DFS (10%)

(1) The frontier is applied by **stack**.

Pseudo code

Visited node set: set()

Frontier : stack

Pop the node at the top of the stack:

If the node is visited, just pop it

If the node is not visited:

Neighbors = expand(node)

For each neighbor:

stack.push(new_path, new_dist)

visited.add(node)

code

```
def dfs(self, src, dst):
    visited = set()
    stack = [[src], 0.0]
    while stack:
        path, cur_dist = stack.pop()
        node_id = path[-1]
        if node_id not in visited:
            if node_id == dst:
                return (path, cur_dist, len(visited))
            neighs = self.graph[node_id]
            for neigh in neighs:
                new_path = list(path)
                new_path.append(neigh.id)
                stack.append((new_path, cur_dist + neigh.dist))
            visited.add(node_id)

    print("Path not found")
    return
```

Part 3: UCS (20%)

- (1) The frontier is applied by **Priority queue**.
- (2) The 1st element of tuple is changed to distance, so the priority queue will sort by distance.

Pseudo code	
<p>Visited node set: set()</p> <p>Frontier : priority queue</p> <p>Pop the node with smallest distance in queue:</p> <p># If the node is visited, just pop it</p> <p># So when the element in the frontier has to update its distance, we just push a new one into the priority queue since the one with smaller value will be retrieved first, and thus the old one will be popped without expanded.</p> <p>If the node is not visited:</p> <p> Neighbors = expand(node)</p> <p> For each neighbor:</p> <p> priority_queue.put (new_dist, new_path)</p> <p> visited.add(node)</p>	
code	
<pre>def ucs(self, src, dst): visited = set() pq = PriorityQueue() pq.put((0.0, [src])) while pq: cur_dist, path = pq.get() node_id = path[-1] if node_id not in visited: if node_id == dst: return (path, cur_dist, len(visited)) neighs = self.graph[node_id] for neigh in neighs: if neigh.id not in visited: new_path = list(path) new_path.append(neigh.id) pq.put((cur_dist + neigh.dist, new_path)) visited.add(node_id) print("Path not found") return</pre>	<p>pq.get() will pop and return the stack element with smallest distance.</p>

Part 4 : A* (20%)

- (1) The frontier is applied by **Priority queue**.
- (2) The distance stored in tuple is **g+h** instead of g in ucs.
(g is referred to distance calculated from src, while h is referred to the heuristic value)
- (3) There's an additional parameter **h_type** in A* function, which is used to identify the heuristic function we should use. (h_type is equal to place_option)

Pseudo code

Visited node set: set()

Frontier : priority queue

Pop the node with smallest distance in queue:

If the node is visited, just pop it

So when the element in the frontier has to update its distance, we just push a new one into the priority queue since the one with smaller value will be retrieved first, and thus the old one will be popped without expanded.

If the node is not visited:

Neighbors = expand(node)

For each neighbor:

priority_queue.put (new_dist + heuristic(node_id), new_path))

visited.add(node)

code

```
def astar(self, src, dst, h_type):
    visited = set()
    pq = PriorityQueue()
    pq.put((0.0 + self.heur[src][h_type], 0.0, [src]))
    while pq:
        cur_gh, cur_dist, path = pq.get()
        node_id = path[-1]
        if node_id not in visited:
            if node_id == dst:
                visited.add(node_id)
                return (path, cur_dist, len(visited))
            neighs = self.graph[node_id]
            for neigh in neighs:
                if neigh.id not in visited:
                    new_path = list(path)
                    new_path.append(neigh.id)
                    new_dist = cur_dist + neigh.dist
                    pq.put((new_dist + self.heur[neigh.id][h_type], new_dist, new_path))
            visited.add(node_id)

    print("Path not found")
    return
```

Part 5: Test your implementation (15%)

Observations																																											
<p>*** Let the number of nodes visited to be cost ***</p> <p>(1) Path length : A* = UCS < BFS << DFS</p> <p>(2) Cost of blue route : A* << DFS < BFS < UCS</p> <p>(3) Cost of orange route : A* << BFS < UCS < DFS</p> <p>(4) Cost of green route : DFS < A* < BFS < UCS</p>																																											
Discussion																																											
<p>(1) Both <u>num(nodes)</u> and <u>distance</u> of the <u>found path</u> are quite <u>large</u> in <u>DFS</u>.</p> <p>(2) <u>BFS</u> contains the <u>smallest nodes</u> in path, but it is <u>not optimal</u> in distance.</p> <p>(3) <u>UCS</u> and <u>A*</u> found the <u>optimal path</u> among all.</p> <p>(4) <u>A*</u> visited much less nodes than others in <u>blue and orange routes</u>.</p> <p>(5) <u>DFS</u> visited the least number of nodes in <u>green case</u>, yet it is not a near path.</p> <p>(6) The path found by UCS and A* are both small, while <u>A* cost less UCS</u>.</p> <p>(7) From the observations, we can conclude that :</p> <p>① Overall, <u>A* cost the least</u> especially in <u>short route</u> (blue and orange).</p> <p>② Regardless of path length, <u>DFS</u> is more <u>efficient</u> in finding <u>long route</u> than short route.</p>																																											

Part 6: Implement another classifier

- (1) The speed has been converted to m/s (Part 0).
- (2) What pushed into queue is a **tuple** with 3 elements: (estimated_time, time, [path_from_src])
- (3) The priority queue will sort by **time+h** instead of distance+h.
- (4) $\text{New_heuristic}(\text{node}) = \text{heuristic}(\text{node}) / \text{node.speed}$.

Pseudo code

```

Visited node set: set()
Frontier : priority queue
Pop the node with smallest distance in queue:
    If the node is not visited:
        Neighbors = expand(node)
        For each neighbor:
            New time = cur_time + (neighbor.dist / neighbor.speed)
            priority_queue.put (new_time+ heuristic(node_id), new_path))
        visited.add(node)

```

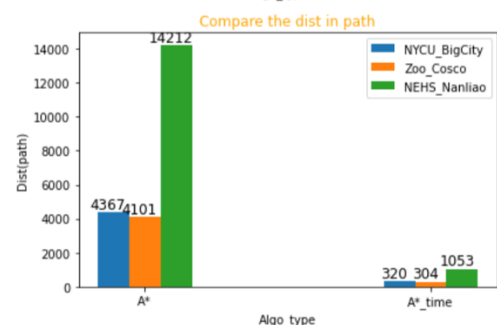

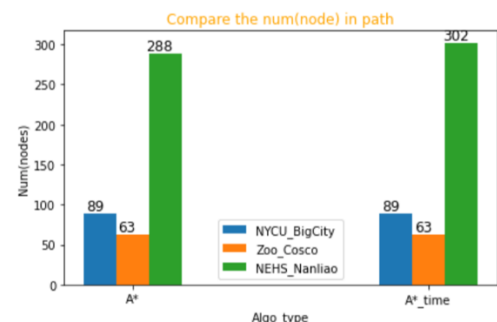

code

```

def astar_time(self, src, dst, h_type):
    visited = set()
    pq = PriorityQueue()
    pq.put((0.0, 0.0, [src]))
    while pq:
        cur_gh, cur_time, path = pq.get()
        node_id = path[-1]
        if node_id not in visited:
            if node_id == dst:
                return (path, cur_time, len(visited)) #time_path, time, time_visited
            neigs = self.graph[node_id]
            for neigh in neigs:
                if neigh.id not in visited:
                    new_path = list(path)
                    new_path.append(neigh.id)
                    new_time = cur_time + (neigh.dist/neigh.speed)
                    pq.put(( new_time + (self.heur[neigh.id][h_type]/neigh.speed), new_time, new_path))
            visited.add(node_id)
    print("Path not found")
    return

```

result

compaision

- (1) Figure 1 :
the number of nodes exist in the path $A^* < A^*_\text{time}$, but there's no significant difference.
- (2) Figure 2:
Skipped since one is evaluated by dist yet the other is evaluated by time.
- (3) Figure 3:
The number of nodes explored by $A^*_\text{time} < A^*$, which means that A^*_time is more efficient.

Part7: Describe problems you meet and how you solve them.

(1) The main problems for me are where to store the node_info and what data structure should I apply.

I ended up writing all of them in a class and modify bfs() to g.bfs(), where g = Graph().

Also, the edges and heuristic functions can be searched and accessed by dictionaries stored in Graph.

(2) Another problem is how should I apply heuristic function in Part 6.

I have tried several (a,b) in $h(x) = a \cdot \text{new_time} + h_dist(x)/b$, while the best result still fails to be less than 320.8723(s), which is worse than TA's result : 320.3284.
